Supporting Information

ABSTRACT: Plasmon-enhanced Raman scattering can push single-molecule vibrational spectroscopy beyond a regime addressable by classical electrodynamics. We employ a quantum electrodynamics (QED) description of the coherent interaction of plasmons and molecular vibrations that reveal the emergence of nonlinearities in the inelastic response of the system. For realistic situations, we predict the onset of phonon-stimulated Raman scattering and a counterintuitive dependence of the anti-Stokes emission on the frequency of excitation. We further show that this QED framework opens a venue to analyze the correlations of photons emitted from a plasmonic cavity.

KEYWORDS: quantum electrodynamics, Raman scattering, SERS, Stokes emission, plasmonics, quantum nanooptics

Surface enhanced Raman scattering (SERS) is a spectroscopic technique in which the inelastic scattering from a molecule is increased by placing it in a hotspot of a plasmonic cavity, where the electric fields associated with the incident and the scattered photons are strongly enhanced (see the schematic in Figure 1a). The difference between the energy of those two photons provides a fingerprint of the molecule, that is, detailed chemical information about its vibrational structure. Since the initial observation of Raman scattering from single molecules, the use of a variety of plasmonic structures that act as effective optical nanoantennas over the last decades has allowed a tremendous advance of this molecular spectroscopy. Metallic particles such as nanoshells, nanorings, nanorods, nanowires, or nano stars, as well as plasmonic nanogap structures formed in particle dimers, nanoparticle-on-a-mirror morphologies, or nanoclusters are among the variety of structures that offer huge and controllable enhancements of the field intensity in their hotspots, boosting the inherently weak Raman scattering intensity, and ultimately enabling the chemical identification and imaging of particular vibrational modes of a molecule with subnanometer resolution. These results suggest that some experiments might have reached the regime where the quantum-mechanical nature of both the molecular vibrations and the plasmonic cavity emerges and call for an adequate theoretical description that goes beyond the classical treatment of the electric fields produced in plasmonic cavities.

In this work, we address the underlying quantum-mechanical nature of Raman scattering processes by quantizing as bosonic excitations both the vibrations of the molecule and the electromagnetic field of a plasmonic cavity. The description of the vibrations through bosonic operators can be justified by considering the harmonic approximation to the energy landscape of the molecule along a generalized atomic coordinate (Figure 1b), such as the length of a molecular bond, for example, C=O. These vibrations interact with the cavity photons through a nonlinear Hamiltonian, reminiscent of that found in optomechanical systems. In this description, the large enhancement of the Raman scattering from a molecule in the plasmonic cavity occurs thanks to the significant shrinking of the effective mode volume of a single photon. On the other hand, such plasmonic systems experience

strong Ohmic losses—that is, they are characterized by very low quality factors (typically $Q \lesssim 10$)—placing these systems deep in the bad cavity regime (see the sketch of a plasmon mode in Figure 1c). This system was recently addressed using a linearization scheme based on the classical Langevin equation for the displacements of plasmon and phonon fields.26

In this work, we complement this approach by employing an exact numerical solution of the quantum mechanical dynamics of the nonresonant Raman scattering process in a plasmonic cavity that fully describes the buildup of incoherent population of vibrations in the molecule, addressing the effect of phonon stimulated Stokes scattering, and furthermore, allows to account for the quantum and classical covariances between the two bosonic fields. This formalism thus predicts a variety of nonlinear quantum effects in the scattered signal that might have already been revealed in different Raman measurements, and opens the door for specific design of experimental configurations that can test, and eventually control, the underlying coherences within SERS.

RESULTS AND DISCUSSION

Theoretical Framework. The interaction between plasmons and vibrations that governs the dynamics of a SERS process can be properly addressed by establishing the Hamiltonian of the system. To derive this Hamiltonian, let us consider the vibrational states of the ground electronic state of the molecule. In a simplified one-dimensional model the potential landscape of this state can be approximated as a displaced harmonic potential. Therefore, the vibrational levels separated by phonon frequency $\omega_m$ can be quantized using the creation and annihilation operators $\hat{b}$ and $\hat{b}^\dagger$. We can thus define a linear polarizability of the molecule along this coordinate as $\delta_{\chi} = R_{\chi} \mathcal{Q}_0^2(\hat{b}^\dagger + \hat{b})$, where $R_{\chi}$ is the element of the Raman tensor and $\mathcal{Q}_0^2$ is the zero-point amplitude of the vibrations. The molecule is coupled to the quantized field of the cavity mode with resonant frequency $\omega_c$ and effective volume $V_{\text{eff}}$, which can be expressed by the plasmon annihilation ($\hat{a}$) and creation ($\hat{a}^\dagger$) operators as $\hat{E} = i \int \frac{d^2 q}{2\pi \epsilon} (\hat{a} - \hat{a}^\dagger)$, where $\epsilon$ is the permittivity of the medium. Thus, the induced Raman dipole $\hat{p}_R = \hat{q}_R \hat{E}$ will be interacting with the cavity field $\hat{E}$, yielding the interaction Hamiltonian $\hat{H}_I = -\hat{p}_R \hat{E}$, which, after dropping the fast rotating terms $\propto (\hat{a}^\dagger)^2$ and $\propto \hat{a}^2$, and redefining the equilibrium position of the vibrations, yields the nonlinear interaction Hamiltonian ($\hbar = 1$): $\hat{H}_I = -g \hat{a}^\dagger \hat{a} (\hat{b}^\dagger + \hat{b})$, with the coupling coefficient $g = R_{\chi} \mathcal{Q}_0^2 \omega_c/(\epsilon V_{\text{eff}})$. This definition can be related to the resonant emitter-plasmon coupling parameter of the Jaynes–Cummings Hamiltonian $g_{JC}$ and the Purcell factor $F_{\text{P}} \propto Q/V_{\text{eff}}$ (see the discussion in Supporting Information). Interestingly, the interaction Hamiltonian $H_I$ is identical to the one used in optomechanical systems, in which the quantized oscillations of a cavity mirror modify the resonance frequency of the cavity.24

It should be noted that this approach is limited to the off-resonant Raman scattering, for which the virtual state mediating the Raman transition (Figure 1b) is strongly detuned from an excited electronic state. Also, our Hamiltonian does not consider Raman processes that involve the effect of the simultaneous excitation or emission of two or more phonons, which may become important for very intense lasers. Furthermore, our model assumes that the plasmonic system can be approximated as a single cavity mode, and described through the canonical quantization scheme. Although this approach should yield an accurate description for many of the plasmonic SERS setups, a more exact description could be offered by a rigorous quantization method which takes into account the exact Green’s function of the system27,28 and would allow consideration of complex plasmonic responses involving many modes.

The coherent evolution of the system, including an additional driving term (laser) at frequency $\omega_l$ is then given by the full Hamiltonian

$$
\hat{H} = \omega_m \hat{b}^\dagger \hat{b} + \omega_c \hat{a}^\dagger \hat{a} - g \hat{a}^\dagger \hat{a} (\hat{b}^\dagger + \hat{b}) + i\Omega (\hat{a}^\dagger e^{-i\omega_l t} - \hat{a} e^{i\omega_l t})
$$

(1)

Throughout the paper $\Omega^2$ will be referred to as a pumping power proportional to the power density of the input laser and the intrinsic parameters of the cavity mode (see the discussion in Supporting Information).

The master equation for the dynamics of the density matrix of the system $\rho$ in the absence of pure dephasing29 reads

$$
\dot{\rho} = \frac{i}{2} [\rho, \hat{H}] + \frac{\kappa}{2} D_\phi [\rho] + \frac{(n_{ph} - 1)\gamma_m}{2} D_\chi [\rho] \\
+ \frac{n_{ph}}{2} \gamma_m D_\chi [\rho] - \frac{n_{ph} \gamma_m}{2} D_\phi [\rho]
$$

(2)

where the last three terms on the right-hand side are Lindblad-Kossakowski terms defined as $30,31$

$$
D_\phi [\rho] = 2\hat{D} \rho \hat{D}^\dagger - \hat{D}^\dagger \hat{D} \rho - \rho \hat{D}^\dagger \hat{D}
$$
describing the decay of the plasmons ($D_\phi$), phonons ($D_\chi$), and the thermal pumping ($D_\chi$) of the phonons by the environment at temperature $T$, with the thermal population $n_{ph} = (\exp(\omega_m/k_B T) - 1)^{-1}$.

In the following, we take the phonon energy $\omega_m = 0.1$ eV and the phonon decay rate $\gamma_m = 1$ meV29 as representative values that characterize vibrational fingerprints, and consider a typical plasmonic cavity with quality factor of $Q = 10$ resonant at $\omega_c = \omega_c$.

2.5 eV, decaying with rate $\kappa = 0.25$ eV (see Supporting Information). The coupling parameter is taken as $g = 1$ meV in accordance with the characteristics of state-of-the-art resonant plasmon-emitter systems (see Supporting Information).

To analyze the dynamics of the system, we follow three complementary approaches. First, we solve directly the master equation in eq 2 by means of numerical calculations,\textsuperscript{22} (taking advantage of low excitation numbers to truncate the Hilbert space). We complement this numerical solution by two other approximate treatments that allow to obtain analytical results, useful to identify the influence of the different parameters in the Raman signal and thus provide simpler expressions to interpret experimental results. In the first analytical approximation, we linearize the Hamiltonian to a purely quadratic form which applies to the weak coupling ($g \ll \kappa$) regime we are interested in, and allows for the analytical treatment (see Supporting Information for details). We note that when solving the linearized Hamiltonian, we do not map the quantum Langevin equation to the classical dynamics equations, as is often done in the analysis of optomechanical systems.\textsuperscript{24} Consequently, this approach provides a complete characterization of the classical and quantum correlations within the system. Finally, to develop the second analytical approach, we apply the quantum noise approach,\textsuperscript{33} in which the vibrations of the molecule are coupled to a bath of fluctuating population of the cavity plasmons.\textsuperscript{25} This formalism allows us to describe the effects of the static and dynamical backaction, which arise when the vibrations of the molecule modify the resonant frequency of the cavity and, therefore, the population term in the Hamiltonian (eq 1).\textsuperscript{24,34}

The static backaction describes the constant, coherent displacement of the state of the vibrations and can be largely neglected in the regime of parameters of interest (see the Methods section for a further discussion). On the other hand, the dynamical backaction (DBA), observed when the incident laser is detuned from the cavity, leads to the heating or cooling of the vibrations.\textsuperscript{24} The quantum noise approach captures those effects, at the price of losing the information about coherences in the molecule-plasmon system.\textsuperscript{24,34} The spectra of emission from the cavity are calculated following Glauber’s photodetection theory,\textsuperscript{35} as $I(t) = a_{dt}(t)S(\omega)$, where the frequency-independent parameter $a_{dt}$ describes the properties of the detection system \textsuperscript{22} and $S(\omega)$ is $\langle a^\dagger a(\omega)\rangle_{ss}$ in the steady state (ss). The two-time correlator is calculated by applying the quantum regression theorem (QRT).\textsuperscript{36}

Let us first focus on the numerical solution. Two spectra of emission from the cavity, calculated for the weak ($\Omega^2 \ll 10^{-2}$ eV$^2$) and strong illuminations ($\Omega^2 = 0.5$ eV$^2$) and for the laser tuned to the cavity ($\Delta \equiv \omega_c - \omega_l = 0$), are shown in Figure 2a and b, respectively. In the inset of Figure 2a we zoom in on the anti-Stokes emission calculated for the environment at $T = 0$ K (dashed line) and $T = 300$ K (solid line); $n_{th}(T = 300)$ $\approx 0.02$. The difference between these plots illustrates the effect of thermal pumping of the vibrational levels by the environment.\textsuperscript{7,26}

To further explore how the signal evolves with the pumping power, we plot in Figure 2c the maxima of the Stokes (blue solid line; in the region of interest this function is independent of the temperature $T$) and anti-Stokes (orange dashed line for $T = 0$ K and orange solid line for $T = 300$ K) emission lines for an increasing $\Omega^2$. In the weak pumping regime ($\Omega^2 \lesssim 10^{-2}$ eV$^2$) for nonzero temperature (solid lines) both the Stokes $S(\omega_s)$ and anti-Stokes $S(\omega_a)$ emission depend linearly on $\Omega^2$, indicating that the anti-Stokes transition originates from the thermally excited vibrational state. For higher driving powers ($10^{-2}$ eV$^2 \lesssim \Omega^2 \lesssim 0.5$ eV$^2$) the anti-Stokes intensities become independent of the temperature, as the phonons are provided primarily by the Stokes transitions (vibrational pumping).\textsuperscript{28} The transition between the thermal and the vibrational pumping of phonons is illustrated in Figure 2d, where we plot the populations of the phonons (green line) in the steady state for $T = 0$ K (dashed line) or $T = 300$ K (solid line). Vertical dashed lines in (c,d) indicate the pumping powers for plots in (a) and (b). All the cases assume $\Delta = 0$.\textsuperscript{28,38}

$$S(\omega_s) = \frac{4\omega_s^4}{\gamma_m^2 + \gamma_m^2} \left( 1 + n_{th} + s_2 \Omega^2 \right) \gamma_m$$

(3)

and

$$S(\omega_a) = \frac{4\omega_a^4}{\gamma_m^2 + \gamma_m^2} \left( n_{th} + s_2 \Omega^2 \right) \gamma_m$$

(4)

with $s_2 \approx [4g/(\kappa\kappa - 2i\omega_m)]^2$ (see Supporting Information for the complete derivation). The first term in the brackets of eq 3 can be recognized as the conventional two-photon cavity-assisted Stokes transition, linearly dependent on $\Omega^2$. As we show in the Supporting Information, by considering the
and the anti-Stokes (Raman emission spectra in the bottom panels of Figure 3), we expect that the calculated centered on the cavity resonance $\Omega$, the enhancement of the electric population of the phonon mode $b$, or the two terms in brackets in eq 4, represents the expected dependence of the Stokes emission on the frequency of the incident laser $\omega_l$. However, to our knowledge, the criterion for the onset of this effect has not been reported in the literature. Interestingly, the classical eq 5 fails to explain the dependence of the anti-Stokes scattering obtained in the full quantum calculations (Figure 3b). For the weakest driving powers (red lines, $\Omega^2 = 10^{-3} \text{ eV}^2$), the $S(\omega_{S}\Delta)$ intensity is found to be the largest for the laser frequency $\omega_l$ on resonance with the cavity $\omega_c$ in the absence of thermal pumping of phonons ($T = 0$); however this maximum appears as red-detuned from the cavity resonance ($\Delta < 0$), the profile $S(\omega_{S}\Delta)$ becomes narrower as we increase the pumping intensity. This behavior results from the buildup of the incoherent population of phonons due to the vibrational pumping and to the dynamical backaction. The latter phenomenon, triggered only when the laser is blue-detuned from the cavity resonance ($\Delta < 0$), has been observed in optomechanical systems and was recently argued to occur in Raman scattering from molecules. We discuss this concept in more detail in the following paragraphs.

Interestingly, the classical eq 5 fails to explain the dependence of the anti-Stokes scattering obtained in the full quantum calculations (Figure 3b). For the weakest driving powers (red lines, $\Omega^2 = 10^{-3} \text{ eV}^2$), the $S(\omega_{S}\Delta)$ intensity is found to be the largest for the laser frequency $\omega_l$ on resonance with the cavity $\omega_c$ in the absence of thermal pumping of phonons ($T = 0$); however this maximum appears as red-detuned from the cavity resonance ($\Delta < 0$), the profile $S(\omega_{S}\Delta)$ becomes narrower as we increase the pumping intensity. This behavior results from the buildup of the incoherent population of phonons due to the vibrational pumping and to the dynamical backaction. The latter phenomenon, triggered only when the laser is blue-detuned from the cavity resonance ($\Delta < 0$), has been observed in optomechanical systems and was recently argued to occur in Raman scattering from molecules. We discuss this concept in more detail in the following paragraphs.

Figure 3. Dependence of the (a) Stokes and (b) anti-Stokes emission and (c) phonon population on the frequency of the incident laser $\omega_l$. In the two leftmost top panels, we show the numerically calculated intensities (a) at the Stokes $S(\omega_{S}\Delta = \omega_l - \omega_c)$ and (b) at the anti-Stokes $S(\omega_{S}\Delta)$ frequencies for the pumping power from $\Omega^2 = 10^{-3} \text{ eV}^2$ (red lines) to $\Omega^2 = 0.25 \text{ eV}^2$ (green lines) and environment temperature $T = 0$ K (dashed lines) and $T = 300$ K (solid lines). In bottom panels in (a, b) the dashed blue lines show the predictions of classical models (eq 5) for (a) $S^{\text{class}}(\omega_{S}\Delta)$ and (b) $S^{\text{class}}(\omega_{S}\Delta)$, whereas the cavity resonances are shown in (a–c) in gray. In (c), we plot the incoherent phonon population $n_{\text{coh}}$ calculated within the quantum noise approach eq 14. Identical results are obtained with the exact numerical calculation. The temperature and intensity for each situation are denoted with the same color code as in (a) and (b).

To further explore the effects of the thermal and vibrational pumping of phonons on Raman scattering, we consider the dependence of the Raman scattering on the detuning $\Delta = \omega_l - \omega_{S}$ of the incident laser. In the typical classical models of SERS, the dependence of the Stokes ($S^{\text{class}}(\omega_{S}\Delta)$) and the anti-Stokes ($S^{\text{class}}(\omega_{S}\Delta)$) emission is determined by the enhancement of the electric field of both the incoming ($|E(\omega_l)/E_{0}(\omega_l)|^2$) and outgoing ($|E(\omega_{S}/\Delta)/E_{0}(\omega_{S}/\Delta)|^2$) photons at the position of the molecule

$$S^{\text{class}}(\omega_{S}/\Delta) \propto \omega_{S}/\Delta^4 \left| \frac{E(\omega_l)}{E_{0}(\omega_l)} \right|^2$$

Assuming that the enhancement is given by a Lorentzian profile centered on the cavity resonance $\omega_c$ with width $\kappa$ (gray curves in the bottom panels of Figure 3), we expect that the calculated Raman emission spectra $S(\omega_{S}/\Delta)$ will depend on the laser frequency as depicted with the blue dashed curves in the bottom panels of Figure 3. In particular, the Stokes signal should be strongest for the incident laser blue-tuned from the cavity. This general result for the Stokes scattering is confirmed by our numerical calculations performed for various pumping powers ($\Omega^2 = 10^{-3} \text{ eV}^2$ to $0.25 \text{ eV}^2$, from red to green lines) and different temperatures ($T = 0$ K as dashed lines and $300$ K as solid lines), as shown in the upper panels of Figure 3a.

However, there are also marked differences: we note that when the laser is blue-detuned from the cavity resonances ($\Delta < 0$), the profile $S(\omega_{S}\Delta)$ becomes narrower as we increase the pumping intensity. This behavior results from the buildup of the incoherent population of phonons due to the vibrational pumping and to the dynamical backaction. The latter phenomenon, triggered only when the laser is blue-detuned from the cavity resonance ($\Delta < 0$), has been observed in optomechanical systems and was recently argued to occur in Raman scattering from molecules. We discuss this concept in more detail in the following paragraphs.

To further explore the effects of the thermal and vibrational pumping of phonons on Raman scattering, we consider the dependence of the Raman scattering on the detuning $\Delta = \omega_l - \omega_{S}$ of the incident laser. In the typical classical models of SERS, the dependence of the Stokes ($S^{\text{class}}(\omega_{S}\Delta)$) and the anti-Stokes ($S^{\text{class}}(\omega_{S}\Delta)$) emission is determined by the enhancement of the electric field of both the incoming ($|E(\omega_l)/E_{0}(\omega_l)|^2$) and outgoing ($|E(\omega_{S}/\Delta)/E_{0}(\omega_{S}/\Delta)|^2$) photons at the position of the molecule

$$S^{\text{class}}(\omega_{S}/\Delta) \propto \omega_{S}/\Delta^4 \left| \frac{E(\omega_l)}{E_{0}(\omega_l)} \right|^2$$

Assuming that the enhancement is given by a Lorentzian profile centered on the cavity resonance $\omega_c$ with width $\kappa$ (gray curves in the bottom panels of Figure 3), we expect that the calculated Raman emission spectra $S(\omega_{S}/\Delta)$ will depend on the laser frequency as depicted with the blue dashed curves in the bottom panels of Figure 3. In particular, the Stokes signal should be strongest for the incident laser blue-tuned from the cavity. This general result for the Stokes scattering is confirmed by our numerical calculations performed for various pumping powers ($\Omega^2 = 10^{-3} \text{ eV}^2$ to $0.25 \text{ eV}^2$, from red to green lines) and different temperatures ($T = 0$ K as dashed lines and $300$ K as solid lines), as shown in the upper panels of Figure 3a.

However, there are also marked differences: we note that when the laser is blue-detuned from the cavity resonances ($\Delta < 0$), the profile $S(\omega_{S}\Delta)$ becomes narrower as we increase the pumping intensity. This behavior results from the buildup of the incoherent population of phonons due to the vibrational pumping and to the dynamical backaction. The latter phenomenon, triggered only when the laser is blue-detuned from the cavity resonance ($\Delta < 0$), has been observed in optomechanical systems and was recently argued to occur in Raman scattering from molecules. We discuss this concept in more detail in the following paragraphs.

Interestingly, the classical eq 5 fails to explain the dependence of the anti-Stokes scattering obtained in the full quantum calculations (Figure 3b). For the weakest driving powers (red lines, $\Omega^2 = 10^{-3} \text{ eV}^2$), the $S(\omega_{S}\Delta)$ intensity is found to be the largest for the laser frequency $\omega_l$ on resonance with the cavity $\omega_c$ in the absence of thermal pumping of phonons ($T = 0$); however this maximum appears as red-detuned from the cavity resonance when the thermal pumping of phonons is produced (at $T = 300$ K). For stronger driving powers, the intensity plots for $T = 0$ and $300$ K start to merge and peak at increasingly blue-shifted frequencies, notably crossing the cavity resonance. As for the supra-linear increase of the Stokes scattering, this surprising property stems from the origin of the vibrations of the molecule and, therefore, can only be applied when these are provided by the heated reservoir (it should be noted, however, that a suitable correction to $S(\omega_{S}\Delta)$ introducing the vibrational pumping has been proposed by Kneipp et al.17).
To understand the dependencies of the Stokes and anti-Stokes emission on the detuning presented in Figure 3a and b, we need to consider the vibrational state of the molecule in detail. Since the linearized Hamiltonian cannot be easily solved analytically for an arbitrary detuning $\Delta$, we develop an alternative analysis of the dynamics of the system based on the quantum noise approach, which also allows to obtain analytical expressions for the Stokes and anti-Stokes photon emission. According to this approach, and similarly to the weak coupling model of a two-level system in a cavity, the rates of relaxation and excitation of vibrations are considered to be proportional to the noise spectrum determined by the characteristics of the plasmonic cavity. This coupling effectively modifies the decay rate of the molecular vibrations to $\gamma_m + \gamma_{opt}$, where the optomechanical damping $\gamma_{opt}$ is dependent on the detuning $\Delta$ and the intensity of the incident laser (see eq 15). Consequently, the Stokes and anti-Stokes emissions reveal similar dependence on the variables shown in Figure 3c and obtained from eq 15. We note that in analogy to other optomechanical systems, we can define a cooperativity-like parameter $C = \gamma_{opt}/\gamma_m$ of the Raman process. For the parameters discussed throughout this work and for blue-tuned laser, $C$ reaches the minimum value of $-0.15$ for $\Delta < 0$ (see Figure S2 in the Supporting Information). For $C \leq -1$ (in the case of laser blue-tuned from the cavity), the system would exhibit phonon lasing.

On the other hand, for red-tuned laser ($\Delta > 0$) we enter the so-called cooling regime in optomechanics, in which the vibrations can be suppressed below the thermal population $n^b_g$. However, because we are not in the sideband-resolved limit ($\kappa \ll \omega_m$), in a typical SERS configuration this effect is suppressed, and $n^b_g$ does not significantly drop below $n^b_g$, as illustrated by the solid lines in Figure 3c.

Last, we focus on an important piece of information regarding the characterization of Raman photon emission that can be obtained from the time- and frequency-resolved correlation $\langle \hat{a}^\dagger(t)\hat{a}(t') \rangle$ between Stokes and anti-Stokes photons emitted from the cavity. In the steady state, this magnitude can be theoretically calculated through intensity–intensity correlations of the filtered output field,

$$g^{(2)}(\omega_1, \omega_2; \tau) = \lim_{t \to \infty} \langle \hat{T}[\hat{A}^\dagger_{\omega_1, t}(t)\hat{A}_{\omega_1, t}(t + \tau)\hat{A}_{\omega_1, \tau}(t + \tau)\hat{A}^\dagger_{\omega_1, \tau}(t)] \rangle$$

where $T$ and $\hat{T}$ denote the time and normal ordering operators, respectively. Furthermore, $\hat{A}_{\omega, t}(t) = \int_{-\infty}^{\infty} e^{i(\omega t - \Gamma t/2)} \tilde{a}(t) \text{d}t$ is the field detected at frequency $\omega$, within a frequency window $\Gamma$, at time $t$. For simplicity we consider $\Gamma_1 = \Gamma_2 = \Gamma$ and place the Lorentzian filters at $\omega_{1/2} = \omega_s/\sqrt{2}$. The photon correlations $g^{(2)}(\omega_1, \omega_2; \tau = 0)$, calculated using a recently developed method, are plotted in Figure 4a as a function of the driving parameter $\Omega^2$ for an environment temperature of $T = 0$ K (dashed lines) and $T = 300$ K (solid lines). The details of the method of calculation of the correlation function are provided in Supporting Information. The coupling parameters $g$ are considered as multiples of $g_0 = \kappa/250$, namely $g = 3g_0$ (blue lines), $g = 2g_0$ (orange lines), $g = 4g_0$ (green lines), with the filter line width $\Gamma = 0.1$ meV. As shown in Figure 4b, for these parameters the physical spectrum of emission $S^{(1)}(\omega) = \langle \hat{A}^\dagger_{\omega, 0}(0)\hat{A}_{\omega, 0}(0) \rangle$ is formed by three peaks: the elastic Rayleigh scattering and inelastic Stokes and anti-Stokes contributions (note that $S^{(1)}$ does not include the explicit dependence on the $\omega^2$ factor). We clearly observe in Figure 4a that for weak coherent pumping and in the absence of thermal pumping (dashed lines), the system exhibits strong bunching statistics, with the two-photon frequency-resolved Stokes-anti-Stokes correlators $g^{(2)}_{\text{ST}}(\omega_1, \omega_2)$ and $g^{(2)}_{\text{AST}}(\omega_1, \omega_2)$ for the temperatures $T = 0$ K (dashed lines) and $T = 300$ K (solid lines), coupling parameters chosen as multiples of $g_0 = \kappa/250$: $g = 3g_0$ (blue lines), $g = 2g_0$ (orange lines), $g = 4g_0$ (green lines), and laser tuned to the cavity $\Delta = 0$.
which is a signature of strongly correlated emission.\textsuperscript{50,51} The physical origin of the strong correlation is discussed in detail in the Supporting Information In short, in the absence of other sources of excitations, the Raman photons are emitted by exchanging a single phonon and are therefore strongly correlated. This process should exhibit a \( \frac{g^2|S|}{\hbar^2}(\omega, \omega_\text{S}) \propto 1/S(\omega_\text{S}) \propto \Omega^{-2} \) dependence, as the rate of coincidences in the detection is determined by the anti-Stokes emission \( S(\omega_\text{S}) \).\textsuperscript{52,53} The results in Figure 4a show this evolution of the correlation for large incident power. As the thermal photons are increasingly created through the absorption of phonons which originate from thermal excitation, leading to the quenching of the correlation. Finally, the dependence of the correlations on the coupling parameter stems from the fact that for small \( g \) (and weak anti-Stokes emission), the filters detect primarily the elastically scattered photons (see Figure 4b), leading to a plateau in \( \frac{g^2|S|}{\hbar^2}(\omega, \omega_\text{S}) \) for small \( \Omega \). We note that these results are consistent with those recently reported by Kasperczyk et al.\textsuperscript{52} from measurements of the Stokes and anti-Stokes pairs emitted from a thin layer of diamond and by Parra-Murillo et al.\textsuperscript{53} from the theoretical analysis of the Raman scattering.

CONCLUSIONS

In summary, we have implemented a fully quantum-mechanical model of the inelastic nonresonant Raman scattering from a molecule placed in a lossy plasmonic cavity. Our analytical and exact numerical calculations point to phenomena which go beyond the standard description of Raman scattering such as (i) the onset of stimulated Stokes emission and (ii) the counterintuitive dependence of the anti-Stokes signal on the detuning of the incident laser from the cavity resulting from the pumping of the molecular vibrations. Furthermore, we demonstrate the strong correlations of Stokes and anti-Stokes pairs emitted from the cavity and analyze the origin of this effect. Finally, we note that our model can be readily applied to a range of physical problems, that is, investigating the Raman scattering of noncoherent light or the quantum correlations induced in the system.

METHODS

Linearization of the Optomechanical Hamiltonian. Let us consider the optomechanical Hamiltonian given in eq 1. If we decouple the cavity from the molecule (putting \( g = 0 \)), the plasmonic system is driven into a steady coherent state with amplitude \( \alpha_\text{s} = \Omega/(\kappa + i\Delta) \). The interaction with these steady-state plasmons dominates the dynamics of the system in the weak-coupling regime as can be seen by the transformation to a displaced basis (with \( |n\rangle \rightarrow |n\rangle \Delta + \langle n\rangle \alpha_\text{s} \)). In the plasmonic system, \( \alpha_\text{s} \) replaces \( \alpha \) and \( \beta \); we can express the coherent dynamics of the system through the Hamiltonian

\[
\hat{H} = \Delta \hat{a}^\dagger \hat{a} + \omega_\text{p} \hat{b}^\dagger \hat{b} - g \alpha_\text{s} \hat{a}^\dagger \hat{b}^\dagger - g (\alpha_\text{s} \hat{a} + \alpha_\text{s}^* \hat{a}^\dagger) (\hat{b} + \hat{b}^\dagger) \\
- g \alpha_\text{s} \hat{b}^\dagger (\hat{b} + \hat{b}^\dagger)
\]  

(9)

As we discuss in the Supporting Information in detail, in the regime of parameters used throughout this work, characterized by weak coupling \( g \), the last nonlinear term can be neglected, allowing us to write the simplified Hamiltonian

\[
\hat{H}' = \Delta \hat{a}^\dagger \hat{a} + \omega_\text{p} \hat{b}^\dagger \hat{b} - g \alpha_\text{s} \hat{a}^\dagger \hat{b}^\dagger - g (\alpha_\text{s} \hat{a} + \alpha_\text{s}^* \hat{a}^\dagger) (\hat{b} + \hat{b}^\dagger)
\]  

(10)

which yields a purely quadratic/Gaussian dynamics and linear quantum Langevin equations. We will refer to \( \hat{H}' \) as a linearized Hamiltonian.

In this new Hamiltonian, the coherent driving of the cavity gives rise (via the nonlinear interaction) to a linear coupling between phonons and plasmons (the last term in eq 10) and an effective coherent driving \( g_{\alpha_\text{s}}b^\dagger \) of the phonon mode. To remove this driving term, we displace the phononic operators in the same way as for the plasmon and obtain a new coherent driving of the cavity (and a renormalized detuning), and so successively. We can capture all orders of this feedback by defining displacements \( \alpha_\text{r} \) and \( \beta_\text{r} \) through the condition that in the displaced basis the Hamiltonian does not contain any linear (driving) terms. Such displaced Hamiltonian can be written as

\[
\hat{H}' = \Delta' \hat{a}^\dagger \hat{a} + \omega_\text{p} \hat{b}^\dagger \hat{b} - g (\alpha_\text{r} \hat{a}^\dagger + (\alpha_\text{r})^* \hat{a}) (\hat{b} + \hat{b}^\dagger)
\]  

(11)

where displacements \( \alpha_\text{r} \) and \( \beta_\text{r} \) are defined by

\[
\alpha_\text{r} = \frac{\Omega}{(\kappa/2) + i\Delta'}
\]  

(12)

\[
\beta_\text{r} = \frac{g \alpha_\text{s}}{\alpha_\text{m} - i(\kappa_\text{m}/2)}
\]  

(13)

and the renormalized \( \Delta' = \Delta - 2g \Re(\beta_\text{r}) \).

Quantum Noise Approach. In the quantum noise approach, the molecular vibrations are coupled to the plasmonic cavity described by the quantum noise density of the plasmon population fluctuations \( \hat{a}^\dagger \hat{a} \) defined as \( S_{\hat{a}}(\omega) = \int_{\pm\infty} \rho_{\text{opt}}(\omega) \hat{F}(\omega) d\omega \) where \( \hat{F} = \hat{a}^\dagger \hat{a} - \langle \hat{a}^\dagger \hat{a} \rangle \) denotes the fluctuations of the plasmon number around the equilibrium, and the average is taken over the state of the uncoupled cavity (\( g = 0 \)). From \( S_{\hat{a}} \) we can obtain the effective relaxation and excitation rates of the vibrations. As a result, the molecular vibrations are in a displaced thermal state. The displacement is given by \( \beta_\text{r} \) and the incoherent population of the thermal state is

\[
n_{\text{coh}} = \frac{n_{\text{opt}}}{\gamma_{\text{opt}} + \gamma_{\text{co}}}
\]  

(14)

(see the previous section and the Supporting Information for details). The second term in eq 14 describes the effective heating of the vibrations by the incoherent population of the cavity (associated with the fluctuations of its population) and dominates the population of phonons in the vibrational pumping regime. It should be noted that this important contribution to \( n_{\text{coh}} \) cannot be derived by assuming a classical form of the cavity field.\textsuperscript{35,64} The optomechanical damping is defined as

\[
\gamma_{\text{opt}} = g^2 \frac{S_{\hat{F}}(\omega_\text{m}) + S_{\hat{F}}(-\omega_\text{m})}{2}
\]  

\[
\times \left\{ \frac{1}{(\Delta - \alpha_\text{m})^2 + (\kappa/2)^2} \right\}^{-1} \left\{ \frac{1}{(\Delta + \alpha_\text{m})^2 + (\kappa/2)^2} \right\}^{-1}
\]  

(15)

with \( n_{\text{coh}} = \frac{\text{det} \hat{F}}{\gamma_{\text{opt}} + \gamma_{\text{co}}} \) denoting the coherent population of the cavity. Here, we simplified the \( \hat{F} \) operator by considering the displaced cavity operators \( \hat{a} \rightarrow \hat{a} + \alpha_\text{r} \) and dropping the quadratic term: \( \hat{F} \approx \sqrt{n_{\text{coh}}} (\hat{a} + \alpha_\text{r}) \).\textsuperscript{34} The first (second) term in the brackets of eq 15 corresponds to the transfer of energy from vibrations to the cavity (from the cavity to the vibrations). The more general form of \( \gamma_{\text{opt}} \) includes the static displacement of vibrations, which can be accounted for by replacing the detuning \( \Delta \) in eq 15 by \( \Delta' \) defined earlier. However, in the regime of parameters of interest in a typical Raman configuration, this correction is negligible. The second term in eq 14 corresponds to the population of vibrational states originating from the coupling to the optical cavity—is proportional to \( n_{\text{rel}} \) with

\[
n_{\text{rel}} = \frac{1}{4\Delta \alpha_\text{m}'}
\]  

(16)
Here, \( \omega' \) is the mechanical frequency corrected for the optical spring effect. This correction, however, can be neglected for the parameters in the regime of interest in SERS.

Finally, we note that in the limit of laser tuned to the cavity resonance \( \Delta \to 0 \), there is no DBA mechanism and the optomechanical damping \( \gamma_{\text{opt}} \) vanishes. In this case, and neglecting the static displacement of vibrations (\( \Delta \approx \Delta' \)), we reproduce within the quantum noise approach the simple expression for the vibrationally pumped incoherent population of vibrations derived earlier from the full quantum-mechanical linearized treatment, thus making both analytical derivations fully consistent

\[
\lim_{\Delta \to 0} n_{\text{coh}}^\omega = n_{\text{th}}^\omega + \frac{4g^2\omega S_{\text{th}}}{K} \approx n_{\text{th}}^\omega + s\Omega \frac{K}{\gamma_{\text{opt}}}
\]

Similarly, the expressions for the photon emission intensities \( S(\omega_S) \) and \( S(\omega_{\text{coh}}) \) obtained in eqs 6 and 7 with application of the quantum noise approach, also match those obtained from the previous analytical derivation (eqs 3 and 4).
